# Nonlinear Regression

We consider the framework implemented in the SPM function *spm-nlsi-GN.m*. It implements Bayesian estimation of nonlinear models of the form

$$y = g(w) + e$$

where  $g(w)$  is some nonlinear function of parameters  $w$ , and  $e$  is zero mean additive Gaussian noise with covariance  $C_y$ . The likelihood of the data is therefore

$$p(y|w, \lambda) = N(y; g(w), C_y)$$

The error *precision* matrix is assumed to decompose linearly

$$C_y^{-1} = \sum_i \exp(\lambda_i) Q_i$$

where  $Q_i$  are known precision basis functions and  $\lambda$  are hyperparameters eg  $Q = I$ , noise precision  $s = \exp(\lambda)$ .

We allow Gaussian priors over model parameters

$$p(w) = N(w; \mu_w, C_w)$$

where the prior mean and covariance are assumed known.

The hyperparameters are constrained by the prior

$$p(\lambda) = N(\lambda; \mu_\lambda, C_\lambda)$$

This is not Empirical Bayes.

# Energies

The above distributions allow one to write down an expression for the joint log likelihood of the data, parameters and hyperparameters

$$L(w, \lambda) = \log[p(y|w, \lambda)p(w)p(\lambda)]$$

It splits into three terms

$$\begin{aligned} L(w, \lambda) &= \log p(y|w, \lambda) \\ &+ \log p(w) \\ &+ \log p(\lambda) \end{aligned}$$

# Joint Log Likelihood

The joint log likelihood is composed of sum squared precision weighted prediction errors and entropy terms

$$\begin{aligned}L(w, \lambda) &= -\frac{1}{2} \mathbf{e}_y^T \mathbf{C}_y^{-1} \mathbf{e}_y - \frac{1}{2} \log |\mathbf{C}_y| - \frac{N_y}{2} \log 2\pi \\ &- \frac{1}{2} \mathbf{e}_w^T \mathbf{C}_w^{-1} \mathbf{e}_w - \frac{1}{2} \log |\mathbf{C}_w| - \frac{N_w}{2} \log 2\pi \\ &- \frac{1}{2} \mathbf{e}_\lambda^T \mathbf{C}_\lambda^{-1} \mathbf{e}_\lambda - \frac{1}{2} \log |\mathbf{C}_\lambda| - \frac{N_\lambda}{2} \log 2\pi\end{aligned}$$

where prediction errors are the difference between what is expected and what is observed

$$\mathbf{e}_y = \mathbf{y} - \mathbf{g}(m_w)$$

$$\mathbf{e}_w = m_w - \mu_w$$

$$\mathbf{e}_\lambda = m_\lambda - \mu_\lambda$$

The Variational Laplace (VL) algorithm, implemented in *spm-nlsi-GN.m*, assumes an approximate posterior density of the following factorised form

$$\begin{aligned}q(w, \lambda|y) &= q(w|y)q(\lambda|y) \\q(w|y) &= \mathbf{N}(w; m_w, S_w) \\q(\lambda|y) &= \mathbf{N}(\lambda; m_\lambda, S_\lambda)\end{aligned}$$

This is a fixed-form variational method.

# Variational Energies

The approximate posteriors are estimated by minimising the Kullback-Liebler (KL) divergence between the true posterior and these approximate posteriors. This is implemented by maximising the following (negative) variational energies

$$I_w = \int L(w, \lambda) q(\lambda) d\lambda$$

$$I_\lambda = \int L(w, \lambda) q(w) dw$$

# Gradient Ascent

This maximisation is effected by first computing the gradient and curvature of the variational energies at the current parameter estimate,  $m_w(old)$ . For example, for the parameters we have

$$j_w(i) = \frac{dl_w}{dm_w(i)}$$
$$H_w(i, j) = \frac{d^2 l_w}{dm_w(i)dm_w(j)}$$

where  $i$  and  $j$  index the  $i$ th and  $j$ th parameters,  $j_w$  is the gradient vector and  $H_w$  is the curvature matrix. The estimate for the posterior mean is then given by

$$m_w(new) = m_w(old) + \Delta m_w$$

# Adaptive Step Size

The change is given by

$$\Delta m_w = -H_w^{-1} j_w$$

which is equivalent to a Newton update (Press et al. 2007).

This implements a step in the direction of the gradient with a step size given by the inverse curvature. Big steps are taken in regions where the gradient changes slowly (low curvature).

# Approach to Limit Example

$$y(t) = -60 + V_a[1 - \exp(-t/\tau)] + e(t)$$

$$V_a = 30, \tau = 8$$

Noise precision

$$s = \exp(\lambda) = 1$$

# Oscillator Example

This example is based on a differential equation describing the evolution of a voltage variable,  $v$ , and a recovery variable,  $r$

$$\begin{aligned}\dot{v} &= c[v - \frac{1}{3}v^3 + r + I] \\ \dot{r} &= -\frac{1}{c}[v - a + br]\end{aligned}$$

This is used in statistics as an example of a difficult optimisation algorithm with multiple local maxima Ramsay et al. (2007).

# Metropolis-Hastings

MH creates a series of random points ( $w(1), w(2), \dots$ ) whose distribution converges to the target distribution of interest. For us, this is the posterior density  $p(w|y)$ . Each sequence can be considered a random walk whose stationary distribution is  $p(w|y)$ .

MH makes use of a proposal density  $q(w'; w)$  which is dependent on the current state vector  $w$ . For symmetric  $q$  (such as a Gaussian) samples from the posterior density can be generated as follows.

# MH update

First, start at some point  $w(0)$  in parameter space. Then generate a proposal  $w'$  using the density  $q$ . This proposal is then accepted according to the standard Metropolis-Hastings procedure.

That is, with probability  $\min(1, r)$  where

$$r = \frac{p(y|w')p(w')}{p(y|w)p(w)}$$

If the step is accepted we set  $w(n+1) = w'$ . If it is rejected we set  $w(n+1) = w(n)$ .

# Adaptive proposal density

We use a zero mean Gaussian proposal density with covariance  $C_S$ . This covariance is initialised to

$$C_S = \sigma C_W$$

where  $C_W$  is the prior covariance and  $\sigma = 1$ .

We then use a three stage procedure comprising (i) scaling, (ii) tuning and (iii) sampling steps in which the scaling and tuning stages are used to optimize the proposal covariance  $C_S$ .

The first two stages are regarded as a burn-in phase and samples from this period are later discarded. At the end of this  $C_S$  is fixed and sampling proper begins.

The proposal covariance is given by

$$C_S = \sigma C_W$$

In the scaling step  $\sigma$  is adjusted as follows.

If the acceptance rate, as measured over the last  $n_s = 100$  proposals, is less than 20 per cent then  $\sigma$  is halved.

If the acceptance rate is greater than 40 per cent  $\sigma$  is doubled.

Otherwise,  $\sigma$  remains unchanged.

The tuning step makes use of adaptive estimation of a covariance matrix  $C_{tune}$  based on a Robbins-Monro update.

At the beginning of the tuning stage we set  $C_{tune} = C_s$ . We then update according to

$$\begin{aligned}\mu_t &= \mu_{t-1} + \frac{1}{n_t}(x_t - \mu_t) \\ \Delta C_{tune} &= \frac{1}{n_t}[(x_t - \mu_t)(x_t - \mu_t)^T - C_{tune}(t-1)]\end{aligned}$$

where  $n_t$  is the number of elapsed iterations in the tuning period. At the end of tuning set  $C_s = C_{tune}$ .

# Potential solutions

Accept that a nonlinear dynamical system model has such a rich repertoire of behaviour, that a model cannot be specified by a dynamical equation alone. One must also specify the range of allowable parameters.

$$\begin{aligned}\dot{v} &= c[v - \frac{1}{3}v^3 + r + I] \\ \dot{r} &= -\frac{1}{c}[v - a + br]\end{aligned}$$

$I$  is input current.

$$\dot{v} = c[v - \frac{1}{3}v^3 + r + I]$$

$$\dot{r} = -\frac{1}{c}[v - a + br]$$

For  $I = 0$  the cell should not spike (need stable fixed point at  $v = 0$ ).

For  $I$  above some threshold there should be an unstable fixed point around which a limit cycle emerges (spiking).
